**Abstract:** The onshore exposures adjacent to modern, offshore passive continental margins may preserve evidence of deformation from the pre-, syn-, and post-rift phases of continental breakup that allow us to investigate the processes associated with and controlling rifting and breakup. Here, we characterize onshore brittle deformation and pre-rift basement metamorphic mineral fabric from onshore Labrador in Eastern Canada in the Palaeoproterozoic Aillik Domain of the Makkovik Province. Stress inversion (1) was applied to these data and then compared to (2) numerical models of hybrid slip and dilation tendency, (3) independent calculations of the regional geopotential stress field, and (4) analyses of palaeo-stress in proximal regions from previous work. The stress inversion shows well-constrained extensional deformation perpendicular to the passive margin, likely related to pre-breakup rifting in the proto-Labrador Sea. Hybrid slip and dilatation analysis indicates that inherited basement structures were likely oriented in a favorable orientation to be reactivated during rifting. Reconstructed geopotential stresses illuminate changes of the ambient stress field over time and confirm the present paleo-stress estimates. The new results and numerical models provide a consistent picture of the late Mesozoic-Cenozoic lithospheric stress field evolution in the Labrador Sea region. The proto-Labrador Sea region was characterized by a persistent E–W (coast-perpendicular) extensional stress regime, which we interpret as the pre-breakup continental rifting that finally led to continental breakup. Later, the ridge push of the Labrador Sea spreading ridge maintained this general direction of extension. We see indications for anti-clockwise rotation of the direction of extension along some of the passive margins. However, extreme persistent N–S-oriented extension as indicated by studies further north in West Greenland cannot be confirmed.

## 1. Introduction

Understanding the geological manifestations of rifting and continental breakup is crucial to further our understanding of the behavior of the crust and lithosphere under extension [1–3] as well as reducing the exploration risk at rifted continental margins [4–6]. The coastal exposures adjacent to modern, offshore passive margins often preserve evidence for rifting- and breakup-related deformation [7–9]. In addition, passive margin settings also provide the opportunity to characterise the relationship between rift-related deformation and pre-rift structures [10,11], concepts which are useful when undertaking offshore studies where such observations are more problematic [11,12]. Inheritance of such pre-existing structural features has been shown by a plethora of previous work to significantly influence various aspects of rift and margin development, including magmatism [13–15], sedimentary basin geometry [11,12,16], and the timing and nature of breakup [17–19].

**Figure 1.** (A) The northeast coast of Labrador, Canada. (B) The area surrounding the study area shown in detail in Figure 3. Both subfigures (A,B) use the topography and bathymetry of [20] V17.1.

Presented herein is an analysis of structural field data obtained in proximity to the town of Makkovik in Labrador, Canada (Figure 1), which is located within the Aillik Domain of the Palaeoproterozoic Makkovik Province (Figure 2), in addition to hybrid slip and dilation tendency analysis and independent regional geopotential stress models based on plate tectonic reconstructions [21].

**Figure 2.** Simplified tectonic framework of central Labrador modified from [22] based on [23], including the location of Figure 3A within the Makkovik Province. Abbreviations: NAC, North Atlantic Craton; BZ, Border Zone; GZ/JB, Granite Zone/ Julianehåb Batholith; NP, Nain Province; MP, Makkovik Province; PsZ, Psammite Zone; PeZ, Pelite Zone; SECP, southeastern Churchill Province; KD, Kaipokok Domain; AD, Aillik Domain; GV, Grenville Province; KMB, Ketilidian Mobile Belt. Inset: The correlation of the Makkovik and Ketilidian orogenic belts has been modified from [24].

The aims of this study were to: (1) determine if onshore deformation exposed in Labrador can be attributed to the Mesozoic-Cenozoic opening of the Labrador Sea, (2) characterise structures that predate Mesozoic rifting, and (3) understand the relationship, if any, of such structures to subsequent rifting. Studies on the role of pre-existing structures in Labrador are required to compliment studies documenting structural reactivation on the conjugate West Greenland margin [7,12,25,26] to determine if both margins display similar expressions of rifting or if different processes were in play, as would be suggested by asymmetric rift models of the Labrador Sea [22].

## 2. Geological Setting

The Labrador Sea separates Labrador in eastern Canada from Southwest Greenland (Figure 2A) and is floored by a small (~900 km wide) oceanic basin [22,27,28]. The Labrador margin provides an ideal location to conduct a study of rift-related deformation for a number of reasons, including near-continuous coastal exposure [22], complementary studies on the conjugate West Greenland margin [7,8,25], and limited production of oceanic crust making conjugate margin studies easier [22,29,30].

Continental breakup in the Labrador Sea occurred at ~62 Ma [31] following a series of rifting events [27,32] that had certainly begun by the Early Cretaceous but had possibly started much earlier in the Jurassic or even the Triassic [33]. The margins of the southern Labrador Sea are considered to be typical non-volcanic margins [27] with igneous rocks limited to deep wells in offshore Labrador [34], major coast-parallel dykes in southwest Greenland [33,35], and their possible minor equivalents in Labrador [36]. The margins of the northern Labrador Sea and Davis Strait are by contrast considered to be volcanic, displaying evidence for seaward dipping reflectors [37] and other widespread magmatism [14,38,39].

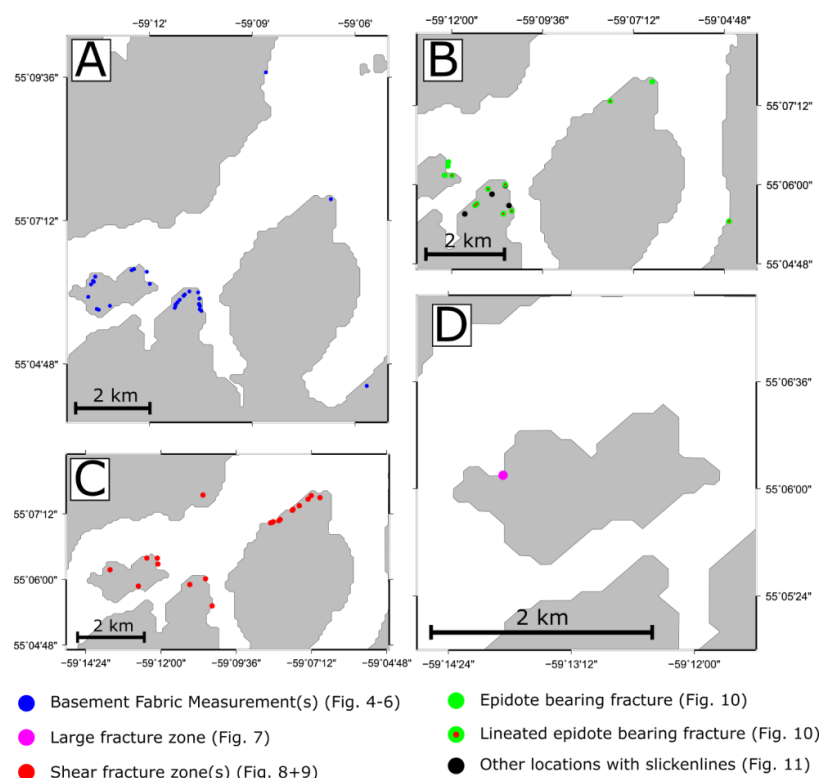

The field data presented in this contribution are from the Palaeoproterozoic Aillik Domain of the Makkovik Province [23,40,41], which is separated from the Nain Province to the northwest by the Kanairiktok shear zone and from the Grenville Province to the south by the Grenville Front [42,43]. The Makkovik Province is characterised as a Palaeoproterozoic accretionary belt and is the smallest defined tectonic component of the Canadian shield [40]. Prior to the opening of the Labrador Sea, the Makkovik Province was adjacent to the Ketilidian mobile belt (KMB; Figure 2), which currently forms part of Southwest Greenland [24,44–46]. The Makkovik Province can be structurally divided into three zones with distinctive geological characteristics; from northwest to southeast, these are the Kaipokok, Aillik, and Cape Harrison domains (Figure 2) [47].

### 3. Field Data Acquisition and Stress Inversion

#### 3.1. Field-Based Methods

##### 3.1.1. Field Data Acquisition

In this study, onshore brittle deformation from onshore Labrador in Eastern Canada was characterised in the Palaeoproterozoic Aillik Domain of the Makkovik Province. All field data presented and analysed herein (Figure 3) were collected during the same field campaign in summer 2015, with the results re-evaluating the potential rift-related magmatism described in [22]. The data include measurements of the orientation of the metamorphic mineral foliation in the basement in addition to measurements from brittle structures, some of which contained kinematic indicators that were used to perform stress inversions that could be used to build structural reactivation models using the MOVE<sup>TM</sup> software (Midland Valley, Glasgow, UK).

**Figure 3.** The location of the data analysed, including: (A) the locations where basement fabric orientation was measured, (B) the locations of the data used in the stress inversion calculations, (C) the locations where zones of shear fractures were recorded and (D) the large fracture zone on Big Island.

### 3.1.2. Stress Inversion of Field Data

Stress inversion (palaeo-stress analysis) uses fault geometry and kinematic data to reconstruct past stress configurations [48]. The main principle of stress inversion is that the slip on a plane occurs in the direction of the maximum resolved shear stress [49]. We employ the MyFault software version 1.05 by Pangea Scientific Ltd. [50] for our stress inversion, applying the minimised shear stress variation method. The minimised shear stress variation calculation is a standard inversion method [51–53] that allows all faults to fail simultaneously, enabling us to calculate the orientation and relative magnitudes (stress ratios) during deformation of the fault set analysed. This method provides a more robust solution than, for example, the simple shear tensor average [50]. Using stress inversion we determined if the observed onshore deformation events are compatible with previous interpretations of the Mesozoic rifting direction prior to the opening of the Labrador Sea [8], and thus elude towards whether the observed brittle deformation was associated with such events.

The key assumption of stress inversion is that the magnitude of the slip stress on a fault is similar for all faults in the set at the time of slip [50], i.e., all deformation is assumed to occur simultaneously within a fault set. For this reason, it is particularly important to determine if all the faults analysed belong to the same deformation event. Thus, previous work devotes considerable effort to separating data into separate fault sets in space and time [52]. However, distinguishing which structures are related to rifting can be problematic given that most margins, including Labrador, have experienced multiple phases of deformation both prior to rifting [8,12,54] and in some cases after rifting, such as fault reactivation during margin inversion [55,56].

For the purposes of this study, two independent stress inversions were performed, ‘inversion A’ and ‘inversion B’. Inversion A was performed on all slip surfaces with slicken lines collected during the fieldwork (i.e., no age constraint), whilst inversion B was performed exclusively on striated slip-surfaces with syn-kinematic epidote mineralisation, which appears to be proximally related to the presence of previously dated dykes [36,57]. This segregation is due to the epidote mineralisation representing the only brittle deformation that could be relatively age-constrained. The close association of this event with the mafic dykes conceivably indicates that the mineralisation is genetically linked to the dykes. It is conceivable that the epidote mineralization event is actually part of the same deformation event as that which produced the other kinematic indicators (inversion A) but that the presence of the epidote is simply an artifact of the proximity of these structures to the dykes. The dykes that contain the epidote mineralisation are classified as alkaline lamprophyre, ultramafic lamprophyre, and carbonatite [58], and they are inferred to belong to the ~590 to 555 Ma intrusive event [36,57]. Thus, ~590–555 Ma is taken to provide an upper age limit for the syn-mineralisation brittle deformation.

The data were first quality-checked in the field by not recording any ambiguous kinematic indicators, and secondly during the analysis by ensuring that none of the angles between the fault planes and the kinematic indicators (misfit angle) exceeded a misfit angle of 25°. When using a misfit angle tolerance of 25°, none of our fault planes required omission from the dataset; moreover, this value is lower than the misfit angle used in some previous studies (e.g., >40° [52]).

## 3.2. Field Observations and Stress Inversion Results

### 3.2.1. Basement Metamorphic Mineral Foliation

A metamorphic mineral foliation was readily observable in many units in the field (Figure 4). The orientation data obtained on the basement rocks in the study area show that the metamorphic fabric is consistently striking approximately N–S (dipping east or west) across the study area (Figure 5). The limited data collected suggest that the folding might be asymmetric with the eastern fold limbs being steeper. The fabric was observed to be predominantly planar, although at some localities this aspect of the basement fabric was indistinguishable and thus no measurements were recorded. Regional geological maps of the Aillik Domain also show many structures with an approximately

N–S orientation, including lithological contacts and shear zones, as well as numerous folds with axial planes of this orientation [41].

**Figure 4.** An example of the metamorphic fabric observed in the basement units on Big Island, ~2 km northwest of Makkovik. Viewing angle is looking down on the exposure with north to the right.

**Figure 5.** Planes to poles for all basement foliation measurements displayed using Kamb contouring. The contour interval is  $2\sigma$ , and the counting area is 14.8% of the Stereonet. Folding is shown by this dataset, with the dominant structural trend of the limbs dipping to the east and west. The axial plane is shown with a dashed line (005/87 E: strike, dip, dip-direction) that was calculated in the Stereonet software (version 9.94 Richard W. Allmendinger, Dept. of Earth & Atmospheric Sciences, 3128 Snee Hall, Cornell University, Ithaca, NY 14853-1504, USA) for OXS (mac operating system) [59].

### 3.2.2. Brittle Deformation

Evidence for brittle deformation was observed across the study area in all lithological units encountered. Fractures were observed ranging in size from a few centimeters to damage zones that are several hundred meters wide (Figure 6). Establishing relative chronologies for the brittle deformation events was challenging due to a lack of distinguishing characteristics and the manifestation of fracture systems varying between lithologies. Also, remarkably few crosscutting relationships enabled observations to be correlated between localities.

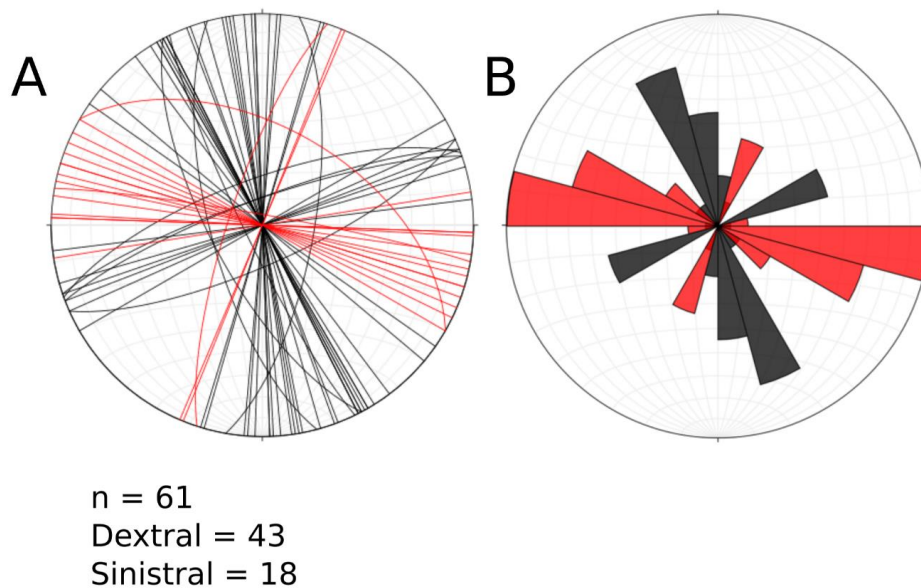

**Figure 6.** Field (A–C) and Google Earth images (D,E) of a zone of extensive intense brittle deformation on Big Island north of Makkovik. Subfigure (E) shows the possible continuation of this zone inland. (A,C) are looking southwest whereas (B) is looking northeast.

Observations of brittle deformation of particular note include: (1) large (>10 m) deformation zones, e.g., the north coast of Big Island (Figure 6); (2) widespread fracture zones in the basement possibly indicating shear deformation (Figures 7 and 8); and (3) those associated with kinematic indicators that were measured are modeled herein (Figures 9 and 10).

**Figure 7.** Examples of the abundant fracture zones in the basement that potentially indicate shear deformation on (A) the north coast of Big Island and (B) the coastline north of Ikey's point (Figure 3).

**Figure 8.** (A) Stereonet showing the orientations of fracture zones, such as those in Figure 7, categorised as either sinistral (red) or dextral (black). Most fracture zones are plotted as vertical as their dip could not be discerned from the field observations. (B) The data from subfigure (A) plotted on a rose diagram using 15° bins (total bins = 24) and divided into two dextral and two sinistral sets of structures. The data presented in this figure were plotted in the Stereonet software for OXS [59].

**Figure 9.** Examples of brittle deformation not associated with the epidote mineralisation that contributed to the data used in inversion A. The quarry near Makkovik shown on subfigure (A) located at 55.0756° N/59.169299° W contained multiple surfaces similar to those in subfigure (B) with readily observable slicken lines, such as those in subfigures (C,D).

Wide zones (>10 m) of intense brittle deformation were observed at several locations, including Big Island (Figure 6), Makkovik Peninsula, Cape Strawberry, and north of Ikey's Point (Figure 3). The large deformation zone on the north coast of Big Island comprises a 100-m wide coastal exposure of mineralised fault breccia of the felsic basement rocks, with a possible continuation inland before a lack of exposure prohibited further observations (Figure 6). Within the mineralised breccia, some proto-cataclasite regions were observed as bands typically from 10 to 30 cm wide but in some cases up to 1 m, which were classified using the system of [60]. A relative age and the possible relationship between the different wide zones of deformation and the other structures described could not be established.

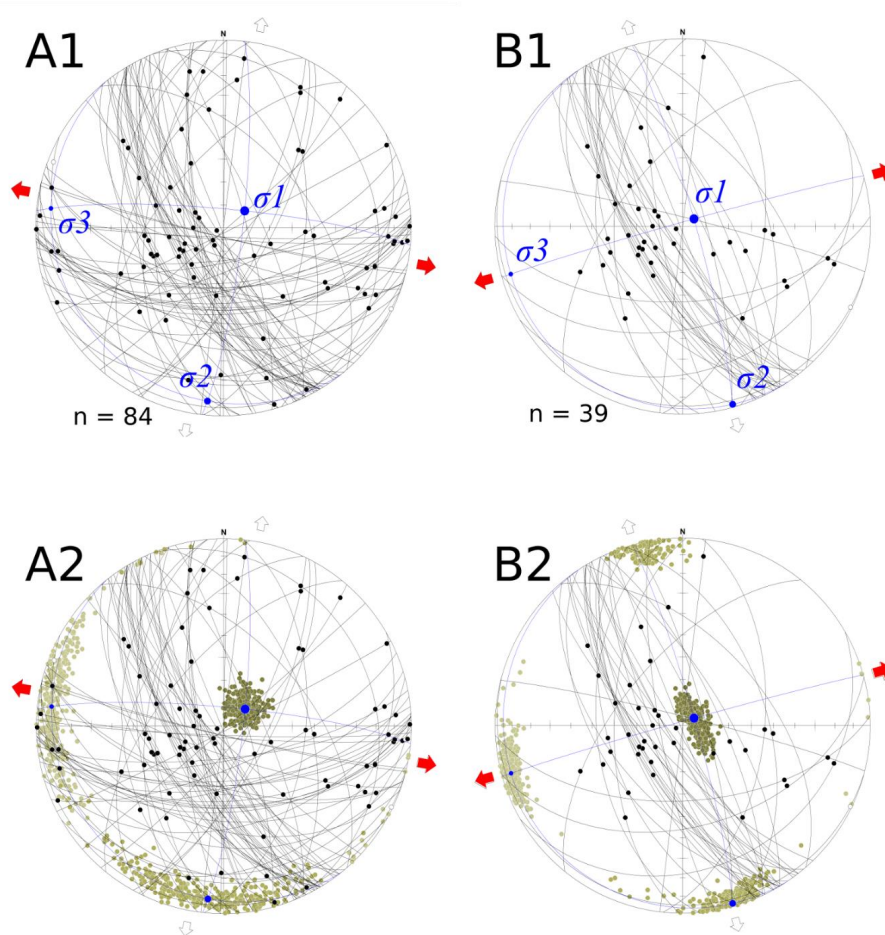

**Figure 10.** Examples of the variability in occurrences of the widespread brittle deformation event associated with epidote mineralisation modelled in this study as inversion B. Subfigure (A1) is located on Big Island (Figure 1) where abundant epidote mineralisation often associated with slicken lines, such as those in (A2), was observed to be widespread. The outcrop in subfigure (B1) was observed on Makkovik Peninsula and shows an example of a mineralised surface in which no kinematic indicators are present. Surfaces such as those in (B1) potentially represent mode I fractures. Subfigures (C1) and (C2) show an outcrop of mafic dyke in Ford's Bight containing pyrite and epidote.

### 3.2.3. Results of Stress Inversion of Field Data

In addition to the wide zones of brittle deformation, smaller, abundant fracture zones in the basement that potentially represent shear deformation were also recorded (Figure 7). These display both a dextral (Figure 7A) and a sinistral (Figure 7B) shear sense. In total, 61 of these fracture zones were observed across the study area, of which 43 were characterised as dextral and 18 were characterised as sinistral (Figure 8). As with the aforementioned wide zones (>10 m) of brittle deformation, a chronology of the sinistral and dextral deformation events was not satisfactorily established, as few localities were observed with cross-cutting relationships between these fracture zones.

Although brittle deformation was observed to be widespread and readily observable (Figures 6–10), reliable kinematic indicators, such as slicken lines, were not observed in conjunction with the majority of this deformation. However, some faults and fractures were observed with kinematic indicators that were sufficient to conduct a stress inversion. Some of the brittle deformation observed with reliable kinematic indicators was associated with significant epidote-dominated mineralisation (Inversion B, Figure 10), whilst at other locations little to no mineralisation was observed to be associated with the deformation (Inversion A, Figure 9). The widespread brittle deformation event modelled in inversion B was characterised by the occurrence of abundant mineralisation dominated by epidote but also including pyrite and chalcopyrite on the mineralised surfaces.

The results of both stress inversions A and B are shown in Figure 11, Tables 1 and 2. A total of 84 measurements were used in stress inversion A, whilst in stress inversion B, although 110 fault and fracture planes were recorded, only 39 were observed to contain measurable kinematic indicators. Thus, the second stress inversion on just the epidote deformation event contains 39 data points. The absence of kinematic indicators does not imply that movement did not occur on the other 71 planes ( $110 - 39 = 71$ ) with epidote mineralisation but that it has not been preserved. The analysed fault data in both stress inversions A and B include tensile, normal, reverse, and strike slip deformation.

**Figure 11.** Stress inversion results for both inversion A and inversion B, with all subfigures denoted with ‘A’ related to inversion A and all subfigures denoted with ‘B’ related to inversion B. Subfigures (A1,B1) display the calculated three principal stress orientations ( $\sigma_1 > \sigma_2 > \sigma_3$ ), along with measured fault planes, associated slicken lines, and the dominant stretching direction (red arrows). Subfigures (A2,B2) show the error calculations associated with the stress inversions. All plots in this figure were produced in MyFault version 1.05.

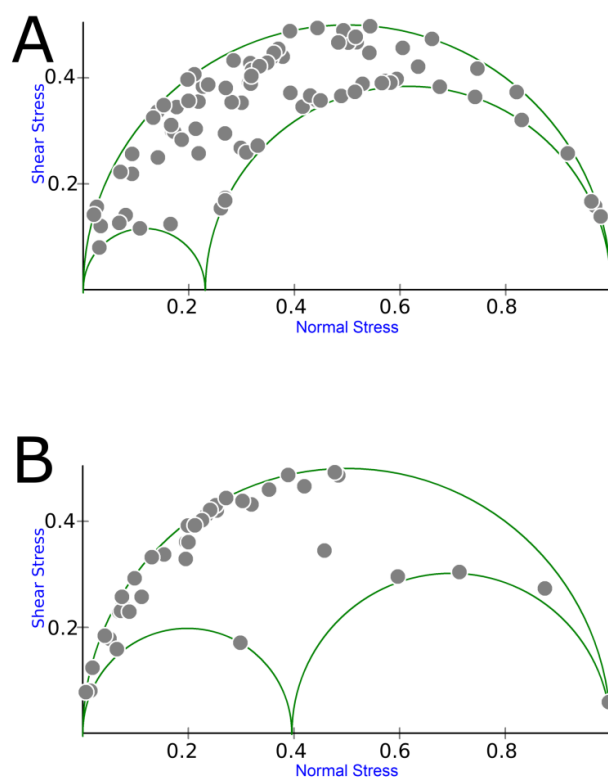

**Table 1.** Calculated principal stress directions from the stress inversion on all modelled data (inversion A).

Principal Stress Axis	Azimuth	Plunge
$\sigma_1$	051°	78°
$\sigma_2$	185°	8°
$\sigma_3$	276°	8°

**Table 2.** Calculated principal stress directions from the stress inversion on the epidote data (inversion B).

Principal Stress Axis	Azimuth	Plunge
$\sigma_1$	056°	84°
$\sigma_2$	164°	2°
$\sigma_3$	254°	6°

The results of stress inversion A (all kinematic data) show that if this deformation all occurred during the same event, it represents an extensional regime, as  $\sigma_1$  (maximum principal stress) is oriented at 051°/78°, whilst  $\sigma_3$  (minimum principal stress) is orientated 276°/08°. This stress field configuration indicates a near E–W extension direction as depicted by the red arrows on Figure 11A1. The results of the stress inversion on just the epidote-bearing faults (inversion B) again indicate that this deformation event occurred during an extensional regime as  $\sigma_1$  (maximum principal stress) is oriented near vertical at 056°/84°, whilst  $\sigma_3$  (minimum stress) is orientated 254°/6°. This stress field configuration indicates an extension direction of approximately ENE–WSW as depicted by the red arrows on Figure 11B1. Plotting the resolved stresses in the slip direction in both stress inversions A and B on Mohr circles (Figure 12) shows that the principal stress orientations in inversion B are better constrained than those of inversion A.

**Figure 12.** Mohr circles (A) and (B) for inversions A and B with the maximum resolved stresses in the fault plane shown in grey. This figure demonstrates that inversion B is a better-oriented dataset to perform a stress inversion on.

## 4. Structural Reactivation Modelling

### 4.1. Structural Reactivation Modelling Methodology

Hybrid slip and dilation tendency analysis was performed on the basement fabric to examine its potential for reactivation during the stress configuration obtained from the stress inversion analysis described above and the extension directions inferred from previous studies [8]. This modelling was carried out using the stress analysis module of MOVE™ developed by Midland Valley. Slip Tendency (or Critical Pressure Perturbation) is the ratio of resolved shear stress ( $\tau$ ) to normal stress ( $\sigma_n$ ) on a particular plane [61–66]. The higher the value, the greater the likelihood the plane will slip (shear failure). Dilation Tendency is a ratio that varies between 0 and 1. The higher the value, the more likely the plane/fracture will dilate (tensile failure). For a plane to dilate in a pure tensile fracture, perpendicular to  $\sigma_1$  (where  $\theta = 0$ ), it must be under stress conditions where:  $\sigma_3 = \sigma_n < 0$  and  $\sigma_3 \geq$  tensile strength of the rock. Alternatively, hybrid failure between shear and tensile fracturing may occur when  $\sigma_3 < \sigma_n < 0$  and  $\sigma_3 < \text{tensile strength of the rock}$ . All modelling was carried out at an assumed depth of deformation of 3 km, a differential stress of 100 MPa, and stress orientations derived from the field data. These values were chosen as a reasonable starting point given the other significant unknowns and the style of deformation and mineralogy. Similar assumptions have been made in [51].

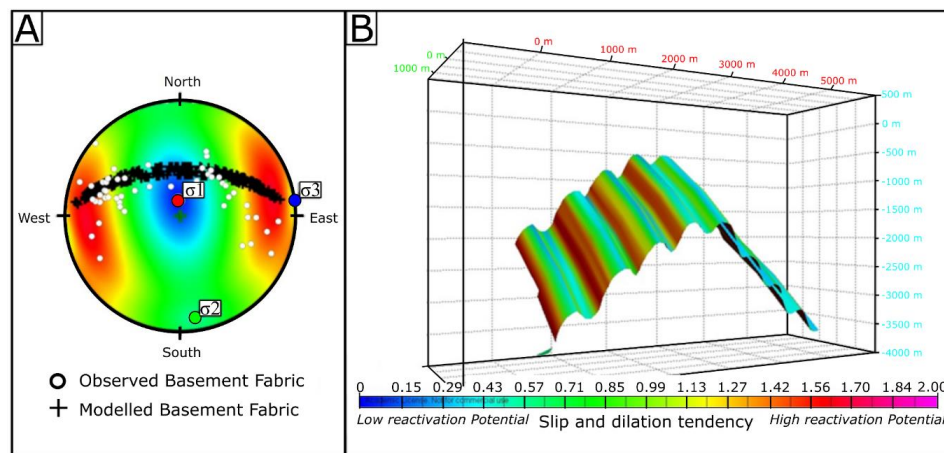

It should be noted that the precise locations of the principal stress directions vary slightly between the results produced using MyFault and MOVE due to the marginally different algorithms used in these pieces of software. The modelling was conducted on a theoretical surface that is representative of the field observations of the basement metamorphic fabric (i.e., a plunging fold with associated 2nd-order folding).

The results of the slip and dilation tendency modelling were then used to identify potential ‘slip surfaces’ or ‘weak zones’ with a high reactivation potential. These surfaces were then modelled using the ‘3D move on Fault’ module of the MOVE™ software to gain insights into the surface expression of reactivating such zones through brittle extensional failure. This allowed for the production of a semi-schematic depiction of how the orientation of pre-existing basement structures may have influenced the manifestation of rifting and margin development.

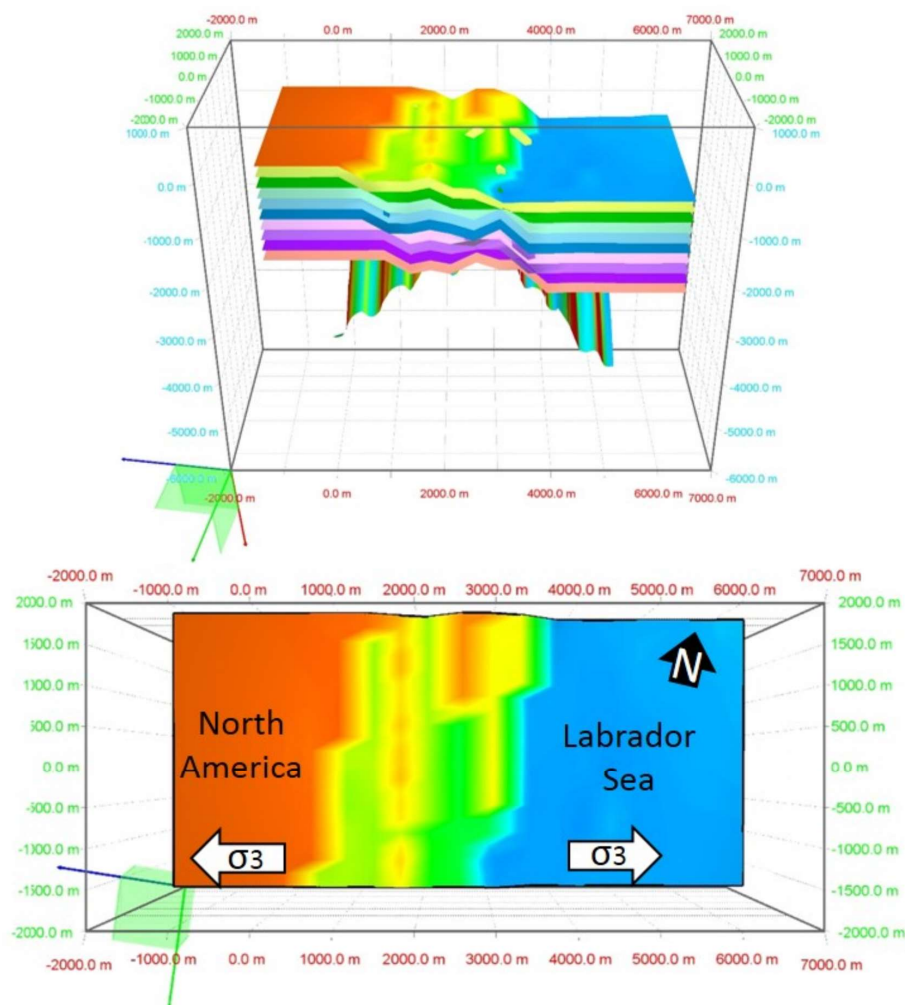

### 4.2. Structural Reactivation Modelling Results

The results of the MOVE™ slip and dilation tendency analysis are shown in Figure 13. Figure 13A shows both the field observations of basement metamorphic fabric (white) and the modelled surface (black) on top of the slip and dilation tendency using the stress ellipsoid calculated in MOVE™. When this basement fabric orientation is considered with respect to the slip and dilation tendency analysis (Figure 13A), it is clear that the fold limbs would have been preferentially orientated to slip and/or dilate at the time of rifting; thus, they have a higher reactivation potential. This is demonstrated graphically in Figure 13B, where the modelled fold (representative of the basement structure of the field area; Figure 5) is shown coloured with regards to the slip and dilation tendency, demonstrating that a reactivation potential is apparent on the fold limbs as opposed to the fold axis. This allows us to tentatively hypothesise that brittle, rift-related structures may have formed parallel to the pre-existing basement metamorphic fabric where weaker zones may have been located.

The results of the MOVE™ extensional analysis are shown in Figure 14. These results demonstrate that incremental brittle failure of the fold limbs may have led to the formation of rift basins oblique to the main extension direction (as observed on this part of the Labrador margin) through the reactivation of the preferentially orientated folded basement fabric.

**Figure 13.** (A) Stereographic projection depicting observed (white) and modelled (black) basement metamorphic fabric measurements along with the slip and dilation tendency. (B) Graphical representation in MOVE™ of the surface that is used in the reactivation modelling and corresponds to the black points in (A). The surface in (B) is coloured with the slip and dilation tendency (reactivation potential) for the stress regime shown in (A).

**Figure 14.** The semi-schematic results of the extensional analysis that was carried out in MOVE™ showing changes to topography as a result of modelled slip on fold limbs.

## 5. Geopotential Stress Field Modelling

### 5.1. Geopotential Stress Field Modelling Methodology

In addition to the analysis of field data and modelling in MOVE<sup>TM</sup>, we investigated the stress field evolution in the entire Northwest Atlantic Ocean (i.e., the Labrador Sea–Davis Strait–Baffin Bay) by means of modelling of lithospheric geopotential stresses through time. Geopotential stresses arise from horizontal gradients in geopotential energy (*GPE*), the integral over the vertical column of a lithostatic pressure anomaly that can be described by:

$$GPE = \int_{-H}^L (L - z) \Delta \rho g \, dz \quad (1)$$

where  $L$  is the depth up to which density variations are incorporated,  $H$  the topographic elevation,  $\Delta \rho$  the vertical density anomaly with respect to a reference lithosphere, and  $g$  is the gravitational acceleration at Earth's surface. In areas far away from active/convergent plate boundaries, geopotential stresses (including ridge push) are by far the most dominant forces acting on the plates.

Our methods to estimate geopotential stresses from lithospheric density structure follow [67,68], with the difference that we require reconstructed lithospheric density models through time (see below). Here, we summarise only the most fundamental principles of the stress calculation.

The asthenospheric–lithospheric density column at each point is estimated as follows: The asthenosphere is defined by expansion of peridotite along an adiabatic gradient  $[\partial T / \partial z] = 0.6 \text{ } ^\circ\text{C/km}$  with a reference potential temperature of  $1315 \text{ } ^\circ\text{C}$ , a thermal expansion coefficient of  $\alpha = 2.4 \times 10^{-5} \text{ K}^{-1}$ , and a reference density of  $3350 \text{ kg}\cdot\text{m}^{-3}$ . The lithosphere and sedimentary layers follow a steady-state conductive geotherm using boundary conditions of  $0 \text{ } ^\circ\text{C}$  at the surface and the adiabatic temperature at the respective LAB (lithosphere–asthenosphere boundary) depth. Representative thermal conductivities, heat production rates, and thermal expansion coefficients are assumed for the mantle lithosphere and the crustal and sedimentary layers lithosphere [67], which are considered to be temperature-dependent [69,70]. We include sub-lithospheric mantle pressure and temperature anomalies, which may change the potential temperature of the mantle adiabat.

A thin sheet approximation of the lithosphere [71–73] is assumed and horizontal tractions at the base of the lithosphere are neglected, as mantle flow patterns and mechanical asthenosphere–lithosphere coupling are poorly constrained.

Given this, the equations of equilibrium of stresses read:

$$\left( \begin{array}{l} \frac{\partial \bar{\tau}_{xx}}{\partial x} + \frac{\partial \bar{\tau}_{xy}}{\partial y} = -\frac{1}{L} \left( \frac{\partial GPE}{\partial x} + L \frac{\partial \bar{\tau}_{zz}}{\partial x} \right) \\ \frac{\partial \bar{\tau}_{yx}}{\partial x} + \frac{\partial \bar{\tau}_{yy}}{\partial y} = -\frac{1}{L} \left( \frac{\partial GPE}{\partial y} + L \frac{\partial \bar{\tau}_{zz}}{\partial y} \right) \end{array} \right) \quad (2)$$

In Equation (2),  $x$  and  $y$  are local horizontal coordinates,  $\bar{\tau}$  is the depth-integrated deviatoric stress,  $\bar{\tau}_{xx}$ ,  $\bar{\tau}_{yy}$ ,  $\bar{\tau}_{xy}$  are horizontal deviatoric stresses,  $L$  is the reference depth, and  $\bar{\tau}_{zz}$  is the vertical sub-lithospheric pressure anomaly. The final equations of the equilibrium of stresses (Equation (2)) are solved using the Finite Element Method [74]. The Earth is parameterised using a dense grid of flat, thick triangles with elastic rheology, forming a spherical shell. The material parameters of each element comprise Young's modulus ( $E$ ), Poisson's ratio ( $\nu$ ), and a uniform thickness ( $L$ ). For detailed information please consult [67].

We follow published approaches to calculate the *GPE* and the corresponding stress field using a reference depth of  $L = 100 \text{ km}$  as an approximation of the elastic layer of the Earth's lithosphere that supports and transmits stresses [75,76].

We use a representation of the present lithospheric structure, including elevation, LAB depth, crustal and sedimentary thicknesses, corresponding densities, as well as sub-lithospheric pressure from [67,77]. We reconstruct the lithospheric structural elements back in time using GPlates (version 2.0) with the global reconstructions from [21].

Additionally, the structural model was modified in the following ways:

- (1) The Greenland ice sheet was subtracted for any time steps >5 Ma.
- (2) Present-day dynamic topography was subtracted from the elevation model used for the reconstruction and for each time-step, dynamic topography was again added from [78] while assuming a maximum dynamic topography of 1000 m for these models.
- (3) The opening oceanic areas in the reconstructions were filled with ocean-age-dependent, average values of surface heat flow, LAB depth, crustal thickness, and topography observed in the present-day lithospheric model for oceanic areas.
- (4) Sediments were subtracted from basins using average sedimentation and subsidence rates over time observed in the Northwest Atlantic [79–84]. The subtracted sediments were then converted and added to a corresponding crystalline crust.

These modifications of the lithospheric model result in a rough character of the different grids in some places. To avoid this, we apply smoothing to the dataset by averaging the values within a running window of radius 50 km (topography and sedimentary layers), 100 km (upper and middle crust), 150 km (lower crust and Moho depth), and 200 km (LAB depth and surface heat flow). Since this analysis was conducted on a  $1 \times 1$  degree grid, this should mostly affect areas in high latitudes for shallower layers, but globally for LAB depth.

Next, a linearised inversion [67,85] changes the assigned free parameters (thickness, densities and heat production of the lithospheric layers, and thermal expansion of the mantle lithosphere) in order to produce a consistent model that fits topography, surface heat flow, and lithospheric isostatic compensation within representative *a priori* errors. The errors for topography and surface heat flow are progressively increased for reconstructions back in time.

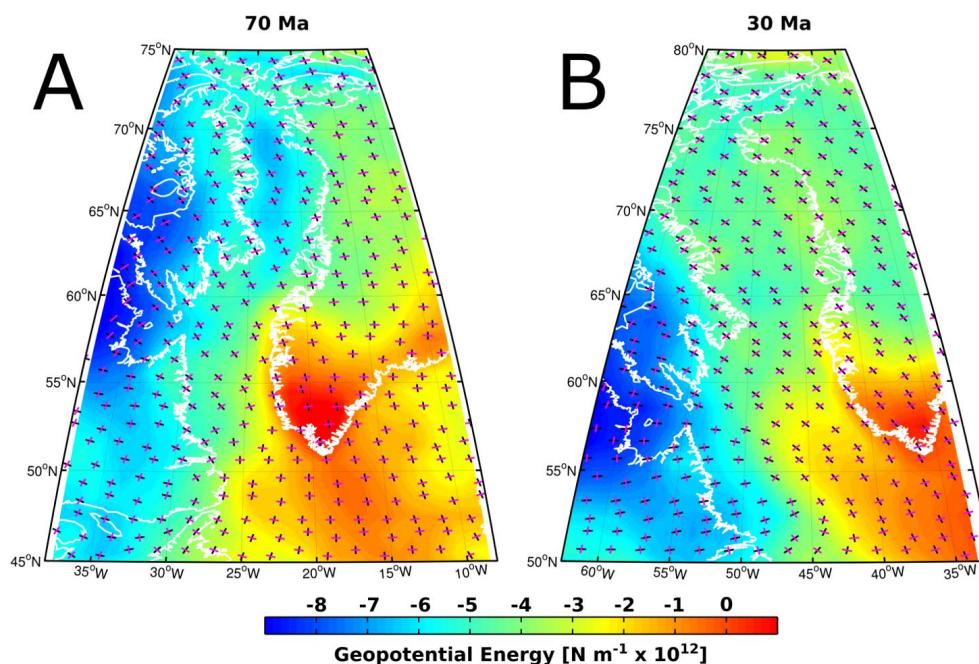

The lithospheric model is built on a large number of assumptions and approximations; hence, the errors are large and impossible to quantify. However, the large-scale, first-order model elements and main sources of geopotential stress changes (opening and closure of ocean basins, the global drift of the continental plates) should be recovered well enough to investigate changes in stress field.

## 5.2. Reconstructed Geopotential Stress Field Results

We have reconstructed models of lithospheric density structure for the Cenozoic and latest Mesozoic. From these results, two representative snapshots are shown at 70 Ma and 30 Ma (Figure 15). The change in lithospheric structure, including far-field stress transfer through the elastic plates, results in quite dramatic changes of lithospheric stress in the region. At 70 Ma, extension (pink bars in Figure 15) is approximately perpendicular to the entire West Greenland and northeastern Canadian margins, corresponding to active rifting and subsequent opening of the Labrador Sea and Baffin Bay. This corresponds to a roughly N–S-oriented compression resulting from low *GPE* in the north and high *GPE* in the south, where the Central Atlantic would be currently opening [86].

In contrast, the stress field at 30 Ma, after the opening of the Labrador Sea and Baffin Bay, only slightly rotated anti-clockwise in Baffin Bay and Davis Strait. However, along the Labrador coast, stress directions changed dramatically to coast-parallel extension from previously coast-perpendicular extension, while in the central and eastern Labrador Sea and Southwest Greenland, ~E–W-oriented extension is retained. This is the effect of the high *GPE* along the formed spreading ridge in the east and the low *GPE* of the North American craton in the west, producing a compressional stress perpendicular to the coastline (coast-parallel extension).

**Figure 15.** Geopotential energy and geopotential stresses calculated for Labrador Sea, Baffin Bay, and environs at reconstructions at (A) 70 Ma and (B) 30 Ma. Pink bars show the direction of maximum horizontal deviatoric stress (extension). Black bars show the direction of minimum horizontal deviatoric stress (compression). High geopotential energy (GPE) (red colours) is observed in areas of high topography and shallow lithosphere. Vice-versa, low geopotential energy corresponds to thick cratonic keels, low topography, and sedimentary basins. Positive sub-lithospheric pressure anomalies, pushing up the lithospheric column, therefore, increase GPE.

## 6. Discussion

### 6.1. Stress Inversion

Overall, both inversions A and B displayed minimal errors in the values of the principal stress orientations (Figure 11(A2,B2)). This is as a result of the dataset containing a sufficient distribution of orientations to constrain the principal stress orientations and the minimal measuring error between the fault planes and kinematic indicators as demonstrated by the use of a relatively low misfit angle compared to previous work [52]. The near-vertical nature of  $\sigma_1$  in both inversion A and inversion B again indicates that the results are realistic for extensional deformation. Error analysis of the results of the stress inversion (Figure 11) demonstrates that there is minimal ambiguity associated with  $\sigma_1$  in both inversions A and B. However,  $\sigma_3$  (and thus  $\sigma_2$ ) is better constrained in inversion B than in inversion A. This may imply that when modelling the whole dataset (inversion A), multiple deformation events could have been incorporated, an interpretation also backed up by the distribution on the Mohr circle (Figure 12). Given the minimal error associated with the stress inversions, the main caveat is that the only dated age constraint is the ~590–555 Ma dykes [36,57].

### 6.2. Geopotential Stress Field Modelling

Our modelling of the geopotential stress field in the Labrador Sea and Baffin Bay allows us to compare palaeo-stress estimations from published literature [8] and those presented in this contribution. We can confirm a persistent coast-perpendicular extension throughout the proto- Labrador Sea and Baffin Bay prior to seafloor spreading. This was previously reported by [8] and has been confirmed by field results presented in this work. However, we cannot confirm the major change of stress direction from E–W to N–S in Central-West Greenland reported by [8], but we do observe such a behaviour

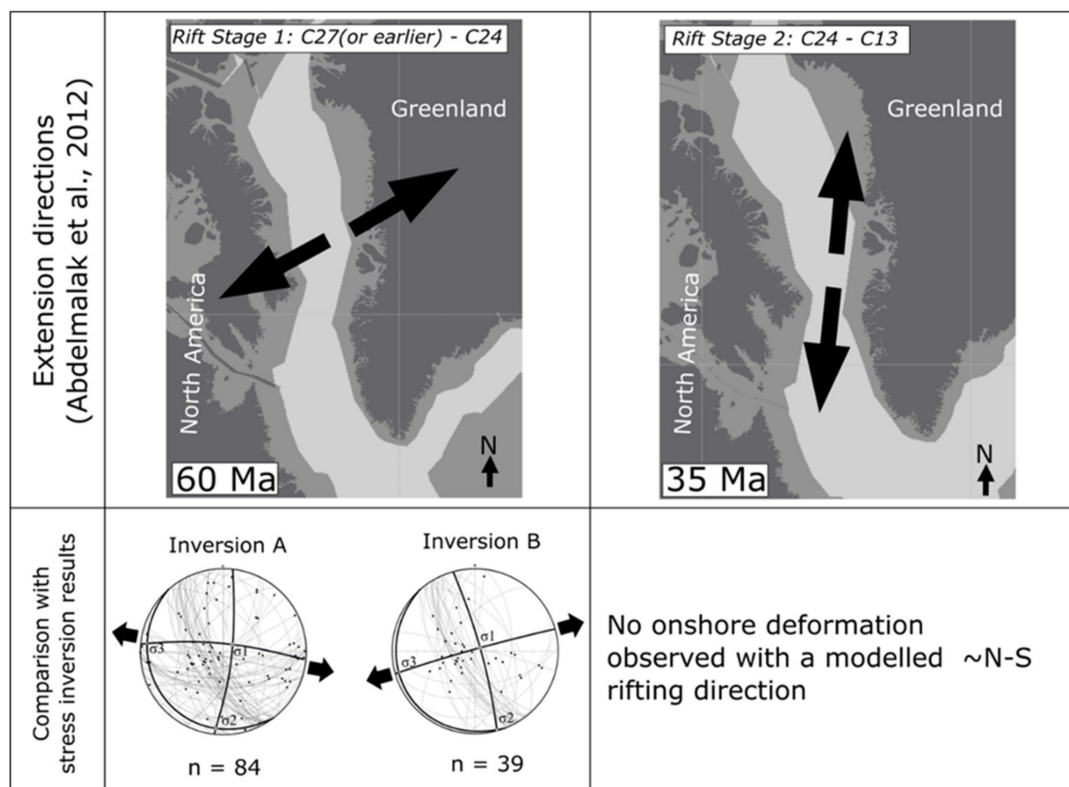

along the Labrador coast. This misfit of the datasets may result from an insufficient reconstructed model (approximations and errors), other effects not considered in our modelling (e.g., horizontal mantle tractions, changing plate tectonic far field stresses), or the observed palaeo-stress measurements representing a more local deviation of the stress field not recovered in our regional lithospheric scale model. The missing geological indications for a switch in stress field from 70 to 30 Ma along the Labrador coast may be due to the low amplitude stresses applied at the passive margin.

### 6.3. An Onshore Expression of Mesozoic Rifting?

Given that a similar extension direction was derived in both inversions A (~E–W) and B (~ENE–WSW), it is possible that all modelled deformation (inversion A) was associated with a singular event in which the epidote mineralisation (inversion B) is a localised mineralogical effect related to the abundant proximal mafic dykes [22,57,58]. However, it should be noted that when the entire dataset is modelled, the error associated with  $\sigma_2$  and  $\sigma_3$  and the spread of data on the Mohr circle (Figure 12) is much greater, possibly implying that inversion A possibly includes deformation related to multiple geological events or that polymodal faulting was in operation. To further test whether all deformation modelled in inversion A is related to a singular Mesozoic event, a significantly larger dataset is required from elsewhere on the Labrador margin, from outside the Aillik Domain within the Makkovik Province, and also from outside the Makkovik Province to ensure that this is not a localised effect.

As previously noted, Abdelmalak, M.M., et al. [8] performed stress inversions based on onshore field data obtained on the conjugate West Greenland margin demonstrating that two key stages of rifting can be identified (Figure 16), a conclusion that is concordant with much of the previous work in this area [7,54,87]. Comparison between the results of the stress inversions in this study (field data and geopotential stress analyses) and those of [8] shows that a similar extension direction has been calculated here as in their rift stage 1 (Chron 27 or earlier to Chron 24) (Figure 16). Rifting during the second stage identified by [8] (~N–S) is inconsistent with the calculated extensional direction in this study. Thus, it is possible that the deformation characterised in the first stage identified by [8] was produced in the same event as the deformation analysed in the stress inversions in this study. However, the data that constitutes inversion A show a series of approximately E–W normal faults that would be consistent with deformation during the second N–S phase of deformation identified by [8]. This implies that inversion A might include brittle deformation from both stage 1 and 2. Furthermore, during rift stage 2, continental breakup had already occurred and thus deformation may have localised onto the Labrador Sea spreading axis and away from the margin, phenomena observed post breakup at other passive margins.

However, other candidate deformation events exist to explain the observed deformation. For example, various Neo-Proterozoic-Cambrian deformation events or even far-field effects of the Appalachian-Caledonian orogeny remain candidates [88,89]. Moreover, it has been noted that during orogenesis, associated deformation can be found thousands of kilometers from the deformation front [90] and thus deformation associated with these events cannot be ruled out. It, however, remains compelling that the results documented herein are in agreement with those from other regions where better chronological constraints were available, e.g., [8].

**Figure 16.** Comparison between the stretching directions in [8] and the stretching direction ( $\sigma_3$ ) produced by the inversions in this study. In addition, the results of the geopotential stress field analysis reproduce a comparable direction for stage 1 but do not resolve stage 2 deformation.

#### 6.4. Basement Fabric and Mesozoic Rifting

It is widely accepted that pre-existing strength anisotropies in the continental crust can have a profound influence on subsequent deformation [12,17,91–94]. In particular, pre-existing basement-hosted faults may represent long-term weakened zones and thus have the potential to be rejuvenated multiple times [25,92,95–97]. However, it is not just basement-hosted faults that can provide a strength anisotropy that may be later reactivated. For example, David Ashby [9] demonstrated that rift orientation in the Santos basin, Southeast Brazil, may have been inherited through the reactivation of a pre-existing basement dyke swarm, while [98] showed that the intrinsic metamorphic fabric of basement terranes of the Northwest Highlands, Scotland may have had a significant influence on fault and fracture orientation during subsequent rifting along the North Coast Transfer Zone during the Permian.

Here, hybrid slip and dilation tendency analysis was performed on the basement fabric to examine its potential for reactivation during the stress configuration obtained from the stress inversion of field data, the geopotential stress analysis, and the extension directions inferred from previous studies [8]. These results have demonstrated that manifestations of ductile deformation, such as folds, also have the potential to induce significant mechanical weaknesses that may be conducive to reactivation during rifting. Thus, fold structures should be considered as candidates for reactivation during subsequent deformation.

## 7. Conclusions

The conclusions of this initial structural and numerical modelling study focusing on potential rift-related deformation in the Aillik Domain of the Makkovik Province, Labrador are that:

(1) The syn-mineralisation (epidote) deformation is modelled to have been produced during an ENE–WSW extensional event. Kinematically, this ENE–WSW extensional event is incompatible with the orientation of the dykes during intrusion so is inferred to be younger than ~590–555 Ma based on the age of mafic dykes which are cross cut by the brittle deformation.

(2) It is possible that the post ~590–555 Ma extensional event produced all brittle deformation analysed herein, with the epidote mineralisation representing a localised effect due to proximity to mafic dykes.

(3) Given the extension directions interpreted from previous work and the geopotential stress field analysis, it is possible that the deformation event(s) documented in this study represent an onshore expression of rifting prior to the opening of the Labrador Sea that was approximately ENE–WSW during the Cretaceous.

(4) The regional metamorphic mineral fabric within the studied part of the Aillik Domain of the Makkovik Province is orientated parallel to the rifting direction inferred by previous studies on the conjugate West Greenland margin and by the stress inversion performed by this work. Such an orientation of the basement fabric and its intrinsic strength anisotropy would have potentially been particularly susceptible to ~E–W rifting as confirmed by the modelling results. Thus, the metamorphic basement fabric may have influenced the orientation of rift development by allowing rifting to easily propagate through the proto-Labrador Sea region.

(5) This work has uncovered evidence for multiple brittle deformation events in the Aillik Domain of the Makkovik Province. Establishing a complete chronology of these onshore deformation events should be a priority of future structural work in this region. This should include attempting to gain an absolute date for the deformation event that was used for the stress inversion in this study. Future work should also aim to collect data and conduct similar analysis elsewhere on the Canadian margin.

(6) The geopotential stress modelling did not reveal an anti-clockwise rotation of the extensional stress component from E–W (in present-day coordinates) to SW–NE, or even to N–S along the West Greenland margin as inferred by previous work. This could be an indication that this reported stress field change may have been a local effect not fully recovered in our model. In contrast, a switch of stress field orientation from E–W to N–S has been modelled at 30 Ma on the Labrador Sea margin that was not seen as a major element of the palaeo-stress analysis.

(7) Finally, future work should expand this analysis throughout the Labrador margin, Baffin Island, and West Greenland to ascertain whether the observations outlined herein (i.e., the role of basement structures during rifting and breakup) are a localised feature of the Makkovik Province or whether they are an intrinsic feature throughout the Labrador Sea–Baffin Bay system.

**Author Contributions:** Conceptualisation, A.P., E.D.D., C.S., J.K.W., K.J.W.M., J.I., and J.J.J.P.; Methodology, A.P., E.D.D., and C.S.; Writing (Review & Editing), A.P., E.D.D., C.S., J.K.W., K.J.W.M., J.I., and J.J.J.P.; Field data acquisition; A.P. and J.J.J.P.; Numerical models: E.D.D. and C.S.

**Funding:** A.P.'s funding for this research was primarily provided by Royal Dutch Shell in the form of a CeREES studentship at Durham University, followed by a postdoctoral fellowship funded by the Hibernia Geophysics support fund at Memorial University of Newfoundland. C.S.'s postdoctoral fellowship at Durham University was funded by the Carlsberg Foundation. The Durham University Center for Doctoral Training (CDT) in Energy, the Durham Energy Institute (DEI), and St. Aidan's College at Durham University are also thanked for their contribution towards the costs of this research. This research would not have been possible without the hospitality of the people of Makkovik, Labrador.

**Acknowledgments:** This research would not have been possible without the advice of Alana Hinchey of the Geological Survey of Newfoundland and Labrador, and the hospitality of the people of Makkovik. Finally, this research was presented at the GAC-NL Annual technical meeting held in St. John's in April 2017 and the authors would like to thank the meeting's organisers for this opportunity.

**Conflicts of Interest:** The authors declare no conflict of interest.
